WORKING PAPER NO. 188

Investing at Home and Abroad: Different Costs, Different People?

Dimitris Christelis[♥] and Dimitris Georgarakos[♠]

Abstract

We investigate US households' direct investment in stocks, bonds and liquid accounts and their foreign counterparts, in order to identify the different participation hurdles affecting asset investment domestically and overseas. To this end, we estimate a trivariate probit model with three further selection equations that allows correlations among unobservables of all possible asset choices. Our results point to the existence of a second hurdle that stock owners need to overcome in order to invest in foreign stocks. On the other hand, we find little evidence for additional pecuniary or informational costs associated with investment in foreign bonds and liquid accounts.

JEL Classification: I0, I1, I2.

Keywords: Foreign assets, household finance, stockholding, multivariate probit, simulated maximum likelihood, selection.

1. Introduction

The strong propensity of investors to concentrate their investments in domestic markets has been well documented (French and Poterba, 1991, Lewis, 1999)¹ and goes against the notion of diversification and the predictions of standard portfolio models like the International Capital Asset Pricing Model (Baele et al., 2007). In the case of stocks, the foregone benefits from international diversification can be substantial even after adjusting for exchange rate risk and border restrictions (Lewis, 1999).²

When studying household portfolio choices it is important to distinguish the decision to invest in a foreign asset from the decision to invest in a domestic one, primarily because assets held domestically can be quite different in terms of participation costs, riskiness, informational, and management requirements from their foreign counterparts. As a result, households have to overcome different participation hurdles before investing in domestic and foreign markets.

With respect to stocks, fixed entry costs have been proposed as a leading explanation of the limited stock market participation by households (Mankiw and Zeldes, 1991, Haliassos and Bertaut, 1995, Vissing-Jorgensen, 2002). Such costs include not only brokerage and monetary fees but also non-tangible costs such as costs of time, costs of processing information as well as costs of picking and monitoring advisors and keeping up with market developments. Investor perceptions about non-tangible costs can be amplified by factors such as lack of familiarity with certain investment products, reducing the likelihood of participation.

¹ Baele et al. (2007), while noting that the extent of the home bias has been decreasing due to globalization and regional integration, still find a large home bias in several countries.

² Several explanations have been proposed for this phenomenon, including trading costs (Tesar and Werner, 1995, Amadi and Bergin, 2006), informational costs and asymmetries (Ahearne et al., 2004, Choe et al., 2005, Dvorak, 2005), poor investment protection and corporate governance (La Porta et al., 1999, Dahlquist et al., 2003, Leuz et al., 2005, Stulz, 2005), transparency in international markets (Gelton and Wei, 2005), real exchange rate volatility (Fidora et al., 2007) and behavioral biases (Grinblatt and Keloharju, 2000, Strong and Xu, 2003). In addition, lack of international diversification has been recently linked to investors' poor understanding about financial information and opportunities available to them (Graham et al., 2005).

It is likely that some of the factors that reflect participation costs and that have been suggested as causes of limited participation in the stock market do not affect in the same way participation in foreign stock markets, for a number of reasons: i) ignorance about the existence of stocks can be quite common in the general population (see Guiso and Jappelli, 2005, for the case of Italy), while we would expect that stockowners are normally aware of the existence of foreign stocks; ii) directly held stocks are assets that are risky, information intensive, and demanding with respect to their management, and are held by a select group of households. These households are very different in terms of resources, investment experience, education, risk aversion, and financial sophistication from the rest of the population (Guiso et al., 2002, Campbell, 2006, Alessie et al., 2007), and thus it is possible that their investment choices differ from those of the rest of the population; iii) foreign stocks can be affected by additional costs related to the monitoring of foreign companies, trading costs (Amadi and Bergin, 2006) as well as the lack of information regarding foreign policies, institutions and accounting practices (Ammer et al., 2006, Covrig et al., 2007, Dvorak, 2005); iv) investors are more prone to buy shares of companies that are geographically closely located (Huberman, 2001); hence such familiarity-related considerations are likely to further discourage investments in foreign owned companies; v) having social interactions has been found to positively affect stock market participation (Hong et al., 2004), possibly because word of mouth information lowers informational costs. The same argument should imply a reverse effect for investments in foreign equity markets, given that only few households hold foreign stocks.

Home bias is not limited to stocks but extends to the case of bonds as well. Burger and Warnock (2006) document that US investors have very limited participation in foreign bond markets (especially those in emerging countries), while Fidora et al. (2007) extend this finding to

several other industrialized economies, typically concluding that the bond home bias is even more pronounced than that for equities.

In this paper, we investigate, using data from the Survey of Consumer Finances (SCF), US households' decision to directly invest in foreign stocks, bonds, and accounts. Our paper makes several methodological and empirical contributions. We document for the first time the existence of significant entry costs affecting household investment in foreign stocks, that are over and above any costs associated with entrance to the stock market in the first place. Evidence for these additional costs comes from the result that, for the select group of investors who hold stocks directly, characteristics that reflect the adequacy of resources and financial sophistication foster investments in foreign stocks. Such characteristics include large economic resources, willingness to assume extra risks, and use of the Internet to obtain financial information, and several empirical studies highlight their role in overcoming participation hurdles in the stock market (see e.g. the contributions in Guiso et al., 2002). Hence, the strong effects of these characteristics on foreign stock ownership, found in the pool of stockholders, point to the existence of separate participation hurdles for foreign stocks.

Second, we study not only stocks, but bonds and liquid accounts as well, and find that, in contrast to stocks, most of the aforementioned characteristics are not associated with investments in foreign bonds and foreign liquid accounts. This result suggests that any additional costs affecting those two foreign assets are not large enough to discourage investing in them.

Third, a key feature of our model is that it addresses the fact that investment in a foreign asset represents an option only for those who decide to invest in the asset irrespective of its provenance. This is consistent with the asset ownership patterns observed in the data, which strongly suggest that households consider the option to invest in a foreign asset type after they

have already invested in the same asset in domestic markets. In other words, households engage in a two-stage decision process, which is potentially subject to selectivity. In addition, our model permits the estimation of all possible pair-wise correlations among the unobservables of each investment decision, and we show that ignoring such correlations can lead to severely biased results.³ The model fits the data quite well, given that its predictions of a variety of conditional and unconditional asset choices track closely the corresponding choices observed in the SCF sample.

While there have been numerous studies examining investments in foreign assets that use macro-level data or data on institutional investors, there have been only few that use household-level survey data.⁴ Bailey et al. (2008), using administrative data from a brokerage firm find that investing experience, higher wealth, and some behavioral biases can lead to international diversification in investors' portfolios. For the purposes of studying investment choices, however, their sample is not representative of the US population because at least 70% of investors therein hold domestic stocks directly and at least 26% hold foreign stocks directly (as opposed to roughly 19% for any direct stockholding and 2% for direct foreign stockholding in the US population according to the SCF). Therefore, it is quite likely that choosing to open a brokerage account is correlated with the decision to directly invest in domestic and foreign stocks, which creates a selectivity problem, or even caused by this decision, in which case there is a simultaneity problem. In addition, the authors do not account for the two-stage decision process involved in foreign asset investment.

³ Most of the empirical literature on household portfolios is based on univariate models for a given asset without taking into account possible spillover effects to the other assets. Exceptions are provided by Perraudin and Sorensen (2000) who simultaneously model demands for money accounts, stocks and bonds, Alessie et al. (2004) who simultaneously study stocks and mutual funds, and Christelis et al. (2011) who study investments across different stockholding modes.

⁴ For studies using macro data see Burger and Warnock (2006), Fidora et al. (2007). For studies that utilize information from institutional investors see Dahlquist et al. (2003), Strong and Xu (2003), Ahearne et al. (2004), Leuz et al. (2005), Ammer et al. (2006).

Karlsson and Nordén (2007) study the foreign investments of a nationally representative sample of Swedish households through their pension accounts, and find that low job security, low economic resources, being male and less educated all lead to home-biased portfolios. They do not, however, model the aforementioned two-stage process involving foreign investment, and they do not distinguish between stocks, bonds and other more liquid investments. Finally, Kyrychenko and Shum (2006) use the SCF to look at determinants of households' decision to invest in foreign stocks and bonds. They model investments in foreign assets as a one step process, by means of standard probit and tobit models, and find that financial sophistication and pessimistic expectations about the domestic economy induce ownership of foreign stocks and bonds (they don't consider liquid accounts). However, by estimating the foreign stock and bond equations on the whole population, they treat the same way households that do not hold foreign assets but have invested in domestic ones and households that do not invest in those assets at all. The objective of our paper is clearly different. We focus on the participation hurdles that affect investments in foreign assets, over and above the hurdles hindering investment in the assets in any form. At the same time, we take into account the fact that households who invest in a given asset have a different configuration of characteristics and attitudes from their counterparts who have not invested in it.

The rest of the paper is organized as follows. Section 2 provides information on the data. Section 3 presents the model setup and discusses the estimation procedure. The empirical results and comparisons of the multivariate probit model with selection against simpler models are presented Section 4. Section 5 concludes.

2. Data

In our analysis we use data from 1995, 1998, 2001, and 2004 waves of the SCF⁵, which is the nationally representative survey that provides the most detailed disaggregated information on US households' financial, real assets, and liabilities. A key feature of the SCF is that it is not subject to top coding of wealthy households, and that the rich, who own the largest share of wealth and are difficult to interview (and thus underrepresented in most surveys), are oversampled. As a result, the SCF is indeed representative of the US population (for more details on the SCF see Kennickell, 2000).

Households are first asked in considerable detail whether they own any stocks, bonds and liquid accounts at all, and if they respond affirmatively they are then asked whether (part of) these investments are foreign.

The question on foreign stocks refers to “stocks in a company headquartered outside the US”, which includes stocks that are cross-listed in US stock exchanges. Companies issuing such stocks must adhere to the same financial disclosure rules as domestic companies. Hence, the informational requirements of investing in stocks of cross listed companies should not be very different from those of domestic companies. Indeed Ammer et al. (2006) and Ahearne et al. (2004) find that cross-listing makes foreign firms considerably more attractive to domestic investors. Moreover, Errunza et al. (1999) show that domestically traded stocks of companies headquartered abroad represent a natural diversification option for spreading international risk. On the other hand, the well-documented propensity of investors to invest in stocks of companies with which they are familiar (e.g. Grinblatt and Keloharju, 2000; Hubermann, 2001) is likely to foster the acquisition of domestic stocks rather than foreign ones, irrespective of cross-listing.

⁵ Questions on foreign asset investments are asked for the first time in 1992, but information on some of the covariates we use in our estimation is only available since 1995.

In our context, cross-listing implies that estimates of the influence that various factors have on households' tendency to invest in foreign stock markets are likely to represent lower bounds on the effects that would have been found if the data had allowed us to focus only on foreign companies that are not cross-listed in the US.

Apart from foreign stocks, the SCF asks households to report whether they own foreign bonds, which are defined in the survey as bonds issued by foreign governments or companies. As for foreign liquid accounts, households are asked whether they hold an account in some currency other than U.S. dollars.

Unfortunately, the SCF does not provide any information on whether households invest in foreign assets through their mutual funds or retirement accounts. As a result, it is not possible to get the full extent of the home bias in US household portfolios from our data. As we will discuss later, however, this feature of the SCF does not affect the consistency of our estimates. Furthermore, tabulations from the SCF data show that only 42% of US households that do not directly own foreign stocks invest in any stocks (domestic or foreign) through mutual funds or retirement plans. In addition, data from the New York Stock Exchange (2001, Table 21), suggest that roughly 55% of investors who have mutual funds or retirement plans invest in foreign stocks through them. Therefore, we would expect less than 25% of the households that do not own foreign stocks directly to invest in them through other investment vehicles.

In addition, Kyrychenko and Shum (2006) point out that, according to the Investment Company Institute (2004), foreign equities account for approximately 13% of all stock investment in IRA's or 401(k)'s. As a result, foreign investment through such vehicles is unlikely to explain the bias against holding foreign assets directly. One should also note that many households who have mutual funds or retirement accounts leave the investment decision

making to the professionals who manage them. From that perspective, the study of investment choices that require active household involvement is more informative about households' attitudes towards foreign assets.⁶

Table 1 reports ownership rates of the three asset categories and their foreign counterparts. A non trivial fraction of households (roughly 10%) does not own any liquid accounts. Directly held stocks have become quite more popular since mid 1990s, while the intervening downswing seems to have slowed down but not completely reversed this trend. Bonds display a different pattern and seem to become less favored over the years. A similar fraction of households, which varies from 1.2 to 3.1 percent, depending on the year, owns foreign stocks and foreign accounts. Ownership of foreign stocks represents, however, an investment option that is chosen by a non trivial number of stockholders (almost 10 percent). On the other hand, only a tiny fraction of households reports ownership of foreign bonds.

A household can invest in foreign assets in a number of different ways. In Table 2, we list all the possible combinations of direct foreign asset investment and their observed proportions among foreign asset holders in the data. We observe that the vast majority of foreign asset holders either invest only in foreign stocks (42.8%) or only in foreign accounts (51%), while very few hold more than one kind of foreign asset.

In Table 3, we compare the economic and demographic characteristics of the two groups of foreign investors with those of all SCF respondents. It is clear that those who invest only in foreign stocks have much larger economic resources, higher education, higher propensity to assume financial risks and higher financial sophistication (as implied by a longer investment

⁶ Ameriks and Zeldes (2004) document widespread inactivity of households as regards changes to the share of stocks in either their retirement accumulation or in their flow contributions in retirement accounts over a ten-year period. On the other hand, Barber and Odean (2000) report that households who directly own stocks through a brokerage account tend to engage in excessive stock trading.

horizon, a more extensive use of the Internet to obtain financial information, and a higher propensity to shop around for financial advice) compared to investors in only foreign accounts and to the whole population. Investors that own only foreign stocks are also older, healthier, more optimistic about the prospects of the US economy, more likely to be white, single males, self-employed, and to work currently or in the past in the financial sector. We also note that those who invest only in foreign accounts are also wealthier, healthier, more educated, more risk loving and more financially sophisticated than the average investor.

The observed dichotomy in foreign asset ownership and the differences in the characteristics of the two principal groups of foreign investors suggest that there are possibly different motives behind investment in foreign stocks and in foreign accounts (e.g. mainly speculative for the former while mostly transactions-related for the latter).

3. The Model

3.1. Description and Variable Specification

The diversified pattern of foreign asset ownership shown in Section 2 suggests different participation thresholds associated with each type of foreign asset; therefore, a disaggregated empirical model is needed in order to study the foreign investment choices of US households. We construct such a model, and its underlying economic decision process is shown in Fig. 1.

First, households decide whether to hold any stocks, bonds and accounts, and all combinations of choices are feasible. If households decide to invest in a given saving vehicle, then they need to decide whether to invest in its foreign component (again, any combination of foreign asset holdings is possible). The structure of the model is consistent with investment patterns in the SCF, in which owners of foreign assets are typically a small subset of the owners

of the assets in any form, who in turn own domestic assets with virtually no exception. Further, it is consistent with the recent findings of Abreu et al. (2011), who, when tracking the behavior over time of investors with accounts in a major Portuguese bank, find that they typically first decide to invest in domestic markets, and only after some time passes do they choose to invest in foreign markets.

As has been shown in the context of lifecycle models with liquidity constraints and background income risk, relatively low fixed entry costs can justify non-participation in the stock market (e.g., see Haliassos and Michaelides, 2003). Fixed entry costs can be tangible (fees required to open a brokerage account) or non-tangible and thus more difficult to quantify (time spent to get information about stocks and their properties, to select a financial advisor, etc.). Vissing–Jorgensen (2002) has provided empirical support to the core prediction of Haliassos and Michaelides’ model, namely that small entry costs can explain limited stock market participation.

Once the cost to enter the stock market has been assumed, the household has the additional option to invest in foreign securities. In practice, only a minority of US households invests in foreign assets (less than 3% in the case of foreign stocks), while virtually all households that own a foreign asset have also invested in its domestic counterpart. This strong observed data pattern is consistent with our modeling strategy: investing abroad is likely to be subject to additional informational and monetary costs, compared to investing in the asset in its domestic form.

As we have already discussed, even small entry costs are sufficient to deter households from investing in domestic stocks. Similarly, entry costs associated with investing abroad (e.g. brokerage fees need to opening a foreign account, time spent to collect information about foreign firms, to monitor investments abroad and to keep up with foreign market developments) and

limited familiarity with foreign companies can prevent ownership of foreign securities. We address empirically the issue of additional costs of foreign securities by showing that household attributes that help circumvent participation costs (e.g., economic resources, education, financial sophistication) are positively associated with foreign stock ownership even for those households that have overcome the entry cost for the asset in question.

Different participation thresholds between the foreign and domestic markets are plausible also in the case of investment in bonds, given that investment in foreign bonds can also be subject to additional costs compared to investment in domestic ones. In addition, while liquid accounts are virtually riskless and frictionless, almost 10% of households do not own such accounts. The existence of monetary costs such as mainly minimum balance requirements and service charges could be one possible explanation. As we will explain further below, our modeling strategy is flexible enough to allow for separate hurdles to be cleared in order to invest in the three assets in question and their foreign components.

The decision process shown in Fig. 1 has the additional advantage of addressing the significant censoring observed in the data, namely the fact that ownership of a given foreign asset is observed only among those households who have decided to invest in the asset in any form. If the econometric model does not take into account the censoring issue, then one is likely to end up with severely biased estimates. For instance, a household chosen at random from the pool of stockholders is more likely to have invested in foreign stocks compared to a household with a similar configuration of characteristics that is drawn from the general population. This can be the case because households who have already invested in stocks are more likely to have acquired information and knowledge through stock management, which can foster investments in foreign equities. As a result, estimating the probability of foreign stockownership on the whole

sample will produce different estimates from those that would have been obtained if the conditioning event of investing in any stocks is taken into account.⁷ Consequently, one should study ownership of foreign assets only on the subsample of all owners of the particular asset in any form, while allowing for the possibility that these owners may form a selected sample, i.e., that the unobservables of the decisions to invest in the asset in any form and to invest in its foreign component are correlated. To put it differently, ignoring the censoring problem is akin to estimating an equation for union membership not on the subsample of workers but on the whole population, which includes not only workers, but also the unemployed and those out of the labor force.

One could in principle consider using a multivariate second stage decision, i.e. after the decision to invest in the asset or not, one would have two separate decisions for investment in domestic and foreign securities. However, this modeling approach would be justified only if all four possible combinations of ownership of domestic and foreign securities were observed in the data. As we have pointed out before, however, there are essentially no households that hold foreign securities without also holding domestic securities. This fact also precludes the use of a nested logit approach, which has the additional disadvantage of not allowing correlations across the different nests (e.g. between stocks and bonds).⁸ Such correlations will prove to be crucial in our analysis, as will be discussed below.

Our model could also be extended to include other investment choices (e.g., mutual funds and foreign mutual funds), which might have unobservables correlated with those affecting direct stockholding. While including other assets would be desirable, we are constrained by the

⁷ See Greene (1998) for a similar argument in the context of credit scoring models.

⁸ The use of a simpler multinomial logit model is also not appropriate, given that in such a model choices are mutually exclusive. On the other hand, a multivariate probit model allows the contemporaneous ownership of several different assets.

fact that information on foreign investments in the SCF exists only for stocks, bonds and liquid accounts.⁹ From a practical point of view, adding a seventh or more equations would make our model even more difficult to estimate. Yet, adding another asset choice would not affect the consistency of our estimates, given that omitting an equation in a multivariate probit model does not lead to inconsistent estimates. It is true, however, that an added equation could increase the efficiency of our estimates, if the unobservables of the added equation were correlated with those of the existing ones.

In the specification for each of the choices pictured in Fig. 1 we control for a rich array of household demographic and economic characteristics and we examine their differential influence on investing in the same asset domestically and abroad, as well as across a range of asset types with varying level of risk. More specifically, we control for age, marital status, having children, health status, and race of the household head. Households with self reported health problems are discouraged from investing in stocks according to Rosen and Wu (2004), who have shown that this effect is not driven by some other factor which influences both health status and portfolio choices. Previous studies report strong race effects on the probability of owning risky financial assets in the US (see for instance, Bertaut and Starr-McCluer, 2002) and this may be mainly attributed to the less aggressive targeting of minorities by the financial sector. Significant race effects have been also identified to influence the probability of a household to own a bank account (see Rhine et al., 2006, who also examine alternative ways to carry out basic financial transactions).

We also control for the educational attainment of the household head. Household portfolio studies from various countries have documented a net positive contribution of

⁹ Households who run their own business are asked about its type (e.g. partnership, a sole proprietorship, etc.) and one item in the list of possible answers is foreign business. However, only a trivially small number of business holders declares ownership of this type of business.

education in investing in information-intensive financial assets, like stocks (see for instance the empirical contributions in Guiso et al., 2002). Education can affect portfolio choice mainly through three channels. First, less educated households are typically less aware of the properties of stocks, which tends to amplify any pecuniary costs associated with stock market participation. Second, education makes it easier to obtain and efficiently process information. Third, highly educated households typically face steeper future income profiles that are likely to influence their asset choices. In addition, there is empirical evidence that education strongly predicts ownership of a bank account (Caskey and Peterson, 1997). The effect may relate to the minimum financial knowledge that is required in picking and managing an account or it may reflect some broader effects like trust in the banking system.

Financial attitudes and practices can affect investment decisions in a way that goes well beyond the effect of life cycle fundamentals (see for instance the discussion in Biliias et al., 2008). To that effect, we use a variable that records if the investor shops around a lot for the best terms when making major saving, investment and borrowing decisions. In addition, we distinguish households who work now or have worked in the past in the financial industry sector because they are likely to be familiar with financial products due to their work environment (Kyrychenko and Shum, 2006).¹⁰ Furthermore, we examine the role of financial information collected through friends, relatives and work contacts as well as Internet use (Bogan, 2008).¹¹ As a measure of risk aversion, we use households' willingness to take more than average financial risks. We also control for having a long investment horizon, namely in excess of ten years.

¹⁰ None of the cross correlations among the dummies of being a college graduate, doing a great deal of shopping around, and working in the financial industry exceeds .09 in the data, which implies that each of these three factors can play a quite distinct role as factors that influence investment choices.

¹¹ We take advantage of the fact that the SCF asks explicitly whether a household gets advice from friends or uses the Internet to obtain financial information, allowing for a direct assessment of their contribution on stockholding.

To account for household economic resources, we use non investment income as well as net real and net financial wealth (thus allowing for distinct effects of accumulated assets that differ in terms of liquidity). It is crucial to control for resources since almost all theoretical models imply a key role of ‘cash on hand’ in determining portfolio choices. Furthermore, in our empirical specification we need to avoid confounding the role of other determinants with that of wealth, when the latter is not adequately accounted for.¹²

We include a dummy for having received an inheritance because it can denote the existence of resources that were made available early in life. In addition, we examine how the intention to leave a bequest can affect investment choices that entail higher risks but also give households a greater potential to achieve a target wealth level that will be bequeathed to their descendants. We also take into consideration several household expectations about the future state of the US economy, domestic interest rates, and their own future real income in order to assess such expectations’ influence on households’ asset decisions in general and on the decision to move funds into foreign assets in particular.¹³ Finally, we include indicators for the survey year.

3.2. Econometric Specification

We empirically implement the three-way foreign investment decision problem, shown in Fig. 1, by using a trivariate probit model with three additional selection equations.¹⁴ The

¹² We control for income, net real and net financial wealth, which all have skewed distributions, by using the inverse hyperbolic sine transformation: $\log(x+(x^2+1)^{1/2})$, which allows for non linear effects and is defined for zero and negative values (see also Pence, 2006). Net financial wealth enters in each equation after deducting the amount of the asset in question in order to avoid possible endogeneity issues.

¹³ French and Poterba (1991), Bohn and Tesar (1996), and Kilka and Weber (2000) argue that expectations about high returns in a particular market make investors to increase the share of their portfolios invested in stocks from that market.

¹⁴ Van de Ven and Van Praag (1981) were the first to estimate a probit model adjusted for selectivity. More recently, Jenkins et al. (2006) have used a bivariate probit model with two selection equations to study consent to give information during a survey interview.

structure of our model is shown in Table 4. Using the notation of Jenkins et al. (2006) the three first stage equations (shown as equations (1), (3), and (5) in Table 4) model respectively the decisions to hold stocks directly, to hold bonds directly, and to have a liquid account. The three second-stage probit equations model the decision to hold foreign stocks given that one directly owns any stocks (equation (2) in Table 4), the decision to hold foreign bonds given that one directly owns any bonds (equation (4)), and finally the decision to have liquid accounts in foreign currency given that one has any liquid accounts (equation (6)). Hence, there are six probit equations in total, and we allow for unrestricted correlations between all six error terms of the underlying latent indices.

The likelihood function distinguishes between eight different cases, which correspond to the eight possible outcomes of the three first-stage equations that denote holdings of any stocks, bonds, and liquid accounts (the likelihood function is discussed in detail in Appendix A.1). We estimate the model by maximum likelihood and pool the 1995, 1998, 2001 and 2004 SCF waves, which contain 17,565 households in total. Given that the SCF uses multiple imputation methods to impute missing values (see e.g. Kennickell, 2000), there are five different implicate datasets for each wave. As a result, we use multiple imputation estimation methods to take into account the additional uncertainty induced by the imputation, i.e., we first perform the estimation and compute robust standard errors within each implicate, and then combine the estimates and standard errors across implicates using the rules described in Rubin (1987). Given that multiple integrals (ranging from three to six dimensions) appear in the likelihood terms, we evaluate them by simulated maximum likelihood using the GHK simulator (Geweke, 1999, Keane, 1994).¹⁵

¹⁵ We use 150 Halton draws and the Stata function `mvnp` to implement the GHK simulator, as described in Cappellari and Jenkins (2006).

Our multivariate probit model with censoring consists in practice of eight multivariate probit specifications estimated in eight different subsamples, as can be readily seen from the likelihood function discussed in Appendix A.1; therefore, it does not require any additional identification assumptions to those underlying a standard multivariate probit model. Moreover, identification in our model is further assisted by the fact that different equations are estimated in different subsamples, whereas in a standard multivariate probit all equations appear in all possible subsamples (see Schmidt, 1981, and Gao et al., 2001, on the usefulness of sample separation information).¹⁶

All the above imply that our full maximum likelihood estimation procedure does not require any exclusion restrictions for identification, as is also the case with the standard multivariate probit model (see also Greene, 2007). We have, however, added a variable denoting a precautionary saving motive¹⁷ as an exclusion restriction, and, as a robustness check, we have also estimated our model without it, and results were essentially identical. This finding is consistent with the fact that the structure of the model is sufficient for identification. In what follows we present the results from the model that includes the precautionary saving motive variable.

As is well known, the convergence of a likelihood function that consists of multidimensional normal integrals evaluated by simulation is not a simple matter. For example, one has to experiment with several initial conditions in order to ensure that the maximum achieved is not a local one. The already complicated likelihood function that is described in Appendix A.1 illustrates why for the moment we are not able to include amounts of foreign asset

¹⁶ For example, in our model, the equation for any stock ownership can be separately identified from the equation for foreign stock investment by using the subsample of those who do not own any stocks, while the equation for foreign accounts can be separately identified from the equation for foreign bonds by using the subsample of those who have any accounts but do not own any bonds.

¹⁷ Households are asked if they save for “a rainy day”.

investment in our model. Namely, the modeling of amounts would require a third stage equation for each asset, i.e., our model would have to include nine equations and several additional parameters reflecting correlations of unobservables.¹⁸ These additions imply several layers of complication that make estimation impractical. To the best of our knowledge, such a multivariate triple-stage model has not been estimated elsewhere in the literature; we leave this question for future research.

When discussing our results, we need to be aware of the fact that regression coefficients in discrete choice models are very difficult to interpret economically because they show the effect of a given regressor on a latent index which has limited economic significance (coefficients are shown in Table A.1 in the Appendix). Making sense of these coefficients becomes even more difficult in the context of a multi-equation discrete choice model with correlated disturbances. This is so because a coefficient in a given equation does not reflect the influence that its associated regressor can have through its presence in the equations for the other choices. This influence could be transmitted to the equation of interest through the cross-correlated equation disturbances.¹⁹ Hence, we will concentrate our discussion of the estimation results on the following economically meaningful magnitudes, derived out of the full multi-equation model: i) the probabilities of different asset choices of interest generated by the model; ii) the marginal effects of the regressors on the probabilities of those asset choices. Throughout our discussion we will be comparing the aforementioned magnitudes as derived from the multivariate probit with selectivity with those derived from estimating three separate probit

¹⁸ These additional correlation terms would include those reflecting selectivity between foreign asset ownership and amount invested.

¹⁹ The discrepancy between coefficients and marginal affects can also occur in other multi-equation discrete choice models in which choices are inter-related (e.g. in multinomial logit/probit).

models with selectivity for stocks (equations (1) and (2) in Table 4), bonds (equations (3) and (4)), and liquid accounts (equations (5) and (6)).²⁰

It is also worthwhile to examine the estimated correlations of the disturbances across equations (shown in Table 5) because they could substantially affect probabilities of asset choices. More specifically, the selectivity term for stocks, ρ_{vu} , is equal to 0.94 and strongly significant. On the other hand, there is no evidence of selectivity for bonds and liquid accounts. These results suggest that stock owners form a selected sample and thus estimating probits of foreign stock ownership among stockholders without accounting for selectivity leads to inconsistent estimates. As for the correlations across the three saving vehicles (stocks, bonds, accounts) we find that the unobservables in the equation for any stockholding are correlated with the unobservables in the equations for bonds and liquid accounts possibly because of some household characteristics and preferences that influence investment in all these assets (see also Alessie et al., 2004). As regards unobservables in the foreign stock equation, they are positively correlated not only with those in the equations for bonds and liquid accounts, but also with unobservables in the foreign accounts equation. Unobservables in the foreign bonds equation, however, are correlated only with those in the foreign liquid accounts equation, possibly because both these assets are less risky than foreign stocks.

We then proceed to check the joint statistical significance of the correlation coefficients. Since our estimation procedure takes into account multiple imputation, we use the F-test suggested by Li et al. (1991) to account for the additional uncertainty induced by multiple imputation. We first perform the test by including all correlation coefficients except three, namely the correlations ρ_{vu} , ρ_{vn} and ρ_{ee} of the errors that respectively correspond to the first and second stage equations for stocks, bonds and liquid accounts and their foreign counterparts and

²⁰ Coefficient estimates from the three two-stage probit models are available upon request.

represent selectivity within each of those three saving vehicles. Hence, if the null hypothesis were not rejected, then one could model foreign asset investment in each of the three saving vehicles independently of what happens with the other two by estimating the aforementioned three simpler separate two-stage probits with selection. However, the value of the F-statistic is equal to 30.83 (p-value: 0.00), and thus the null hypothesis is strongly rejected. When we add the three correlation terms denoting selectivity (i.e., ρ_{vu} , ρ_{vn} and ρ_{ee}) to the joint test of correlations, the F-statistic is equal to 34.22 (p-value: 0.00), again strongly rejecting the null. Hence, in our context and in contrast to what happens in Jenkins et al. (2006), we conclude that one cannot ignore the correlations of the unobserved factors across equations when estimating the probabilities of asset choices of interest.

The multivariate nature of the model permits the computation of a wide range of asset choice probabilities as follows: as explained in more detail in Appendix A.1, any asset combination is reflected by a particular 6-tuple of values of the six-element vector (S, FS, B, FB, A, FA) and has a probability given by

$$P(S, FS, B, FB, A, FA) = N_p(k_S C \hat{\alpha}, m_{FS} D \hat{\beta}, k_B G \hat{\gamma}, m_{FB} H \hat{\delta}, k_A X \hat{\zeta}, m_{FA} Y \hat{\theta}, \bar{\rho}) \quad (13)$$

with $S \geq FS, B \geq FB, A \geq FA$,

$$k_S = 2 \cdot S - 1, k_{FS} = 2 \cdot FS - 1, k_B = 2 \cdot B - 1,$$

$$k_{FB} = 2 \cdot FB - 1, k_A = 2 \cdot A - 1, k_{FA} = 2 \cdot FA - 1,$$

$$m_{FS} = k_{FS} \cdot I(S = 1), m_{FB} = k_{FB} \cdot I(B = 1), m_{FA} = k_{FA} \cdot I(A = 1),$$

$$p = |k_S| + |m_{FS}| + |k_B| + |m_{FB}| + |k_A| + |m_{FA}|,$$

$$\bar{\rho} = (k_S k_B \hat{\rho}_{uv}, k_S k_A \hat{\rho}_{ue}, k_B k_A \hat{\rho}_{ve}, k_S m_{FS} \hat{\rho}_{vu}, m_{FS} k_B \hat{\rho}_{uv}, m_{FS} k_A \hat{\rho}_{ue}, k_S m_{FB} \hat{\rho}_{vn}, k_B m_{FB} \hat{\rho}_{vn}, m_{FB} k_A \hat{\rho}_{ne}, k_S m_{FA} \hat{\rho}_{ve}, k_B m_{FA} \hat{\rho}_{ve}, k_A m_{FA} \hat{\rho}_{ee}, m_{FS} m_{FB} \hat{\rho}_{un}, m_{FB} m_{FA} \hat{\rho}_{ne}, m_{FS} m_{FA} \hat{\rho}_{ue})$$

where $m_{FS} D \hat{\beta}, m_{FB} H \hat{\delta}, m_{FA} Y \hat{\theta}$ do not appear in N_p when $S=0, B=0, A=0$, respectively. The same is true for all terms in $\bar{\rho}$ involving $m_{FS}, m_{FB},$ and m_{FA} . Given that asset combinations are

mutually exclusive, a set of asset combinations has a probability equal to the sum of the probabilities of the individual combinations. Therefore, the probability of any asset choice is equal to the sum of the probabilities of all asset combinations in which this choice is observed. As an example, the conditional probability of holding foreign stocks given ownership of stocks in any form can be expressed as the sum of the probabilities of all asset combinations that include investment in foreign stocks, divided by the corresponding sum of probabilities for investment in any stocks, that is,

$$P^C(FS = 1/S = 1) = \frac{P(S = 1, FS = 1)}{P(S = 1)} = \frac{\sum_{B=0}^1 \sum_{FB=0}^1 \sum_{A=0}^1 \sum_{FA=0}^1 P(1, 1, B, FB, A, FA)}{\sum_{FS=0}^1 \sum_{B=0}^1 \sum_{FB=0}^1 \sum_{A=0}^1 \sum_{FA=0}^1 P(1, FS, B, FB, A, FA)} = \frac{N_2(C'\hat{\alpha}, D'\hat{\beta}, \rho_{vu})}{N(C'\hat{\alpha})} \quad (14)$$

The reduction in the dimensionality of the normal integrals implied by the last equality in (14) does not extend in general to more complicated choices of interest, e.g. to the probability of owning any foreign asset, which is equal to

$$P^C(AFI = 1) = \sum_{S=0}^1 \sum_{\substack{FS=0 \\ S \geq FS}}^1 \sum_{B=0}^1 \sum_{\substack{FB=0 \\ B \geq FB \\ FS+FB+FA > 0}}^1 \sum_{A=0}^1 \sum_{FA=0}^1 P(S, FS, B, FB, A, FA) \quad (15)$$

where AFI denotes investment in any foreign asset, and the summation is over all asset combinations in which at least one foreign asset is held.²¹

Marginal effects are computed as the change in the probabilities when there is an appropriately defined change in the value of the regressor.²² We estimate probabilities and

²¹ Replacing this summation with the sum of the three unconditional probabilities of owning foreign stocks, foreign bonds and foreign accounts would involve double counting of several asset combinations. In our calculations we always use the sum of probabilities of the relevant asset combinations in order to calculate probabilities of asset choices.

marginal effects and their standard errors via Monte Carlo simulation (see Appendix A.2 for details).

4. Empirical Results

In this section we present predictions of various asset choices of interest, and marginal effects (or semi-elasticities) for each of the three assets and their foreign counterparts. In particular, Table 6 compares actual and predicted population proportions of households who make various asset choices, while Table 8 presents marginal effects on the probability of owning stocks and conditional marginal effects on the probability of owning foreign stocks, (conditional on owning any stocks), from both the two stage probit with selection (columns 1-4) and the multivariate probit with selection (columns 5-8). Similar results for bonds and accounts are summarized by Tables 9 and 10, respectively. By focusing on conditional probabilities of second-stage foreign asset choices we can disentangle the effects of household characteristics on these choices that exist over and above their corresponding effects on first-stage decisions. In other words, we can see whether there are any additional participation thresholds faced by prospective investors in the foreign component of a given asset, even after investors have overcome any informational or pecuniary obstacles of investing in the asset in any form.

4.1. Model Performance

A useful check of the fit of our model would be to compare its predictions with the outcomes observed in the data. To this effect, in column 1 of Table 6 we report the observed

²² For dummy variables the marginal effect is defined as the weighted mean difference across households in the predicted probability when the regressor is equal to one and when the regressor is equal to zero. For income- and wealth-related continuous variables we calculate weighted median semi-elasticities instead of weighted average ones because computation of semi-elasticities requires multiplication of the marginal effect with the level of the financial variables, which have distributions with a large positive skew. We utilize sample weights provided by the SCF in all these calculations in order to make our results representative for the entire population.

population proportions of households making various asset choices and we compare them with the predictions from the simple two-stage probits with selection, shown in column 2, and with those from the multivariate probit with selection, shown in column 4 (details on the calculation of predicted proportions are provided in Appendix A.3).

We observe that the multivariate model with selection does in general a good job of predicting sample proportions, even for asset choices with small actual prevalence (with the exception of the probability of owning foreign stocks conditional on owning foreign liquid accounts). The good predictive performance of the multivariate probit is all the more notable given that maximization of its likelihood function does not lead to any automatic equality of actual proportions with average predicted probabilities, as is the case with a simple probit. In addition, our model gives significantly better predictions than the simple independent two-stage probits for the probabilities of holding foreign stocks conditional on holding any stock, and the corresponding conditional probability for bonds. The superiority in the predictions of the multivariate probit model is even more apparent for probabilities involving choices across the three different saving vehicles (e.g. the probabilities of holding any stocks conditional on owning any bonds, of owning foreign stocks given ownership of foreign accounts, of owning any foreign asset, etc.). The reason for the generally very poor predictive performance of the independent two-stage probits in those cases (with the exception of the probability of holding foreign bonds conditional on holding foreign stocks and the probability of having liquid accounts conditional on having any foreign asset, for which the two models give similar predictions) is precisely the failure to take into account the correlations in the unobservables across the different saving vehicles.²³

²³ In order to compute probabilities of choices spanning two or more of the three saving vehicles that are generated by the three independent two-stage probits, we proceed as follows: i) any probability of a choice in a given saving

One other way to check the performance of our multivariate model is to compare the marginal effects of our variables of interest on the probability of owning any foreign asset²⁴ to the corresponding marginal effects derived from a simple probit for any asset ownership (which does not distinguish across paths to the ownership of different foreign asset types). Results are presented in Table 7, in which the marginal effects derived from the simple probit are shown in column (1), whereas those derived from our multivariate model are shown in column (3). We note that the marginal effects are very similar in sign, size, and patterns of significance. This similarity suggests that the complex structure of our model leads to results that are essentially the same with those derived under a simple probit model that only estimates the likelihood of owning any foreign assets.²⁵ Nevertheless, our model represents an advance on this simpler model because it treats separately three foreign assets that are very different from one another, it allows households to clear different participation hurdles in order to invest domestically and abroad, it takes into account selectivity, and it allows all possible correlations among unobservables affecting the different asset investment decisions.

4.2. Stocks and Foreign Stocks

Marginal effects from the first stage regression of the multivariate probit specification on stock ownership are shown in Table 8, column 5. Our results are in line with existing findings in the empirical household portfolio literature for the US (e.g. Bertaut and Starr-McLuer, 2001). Household characteristics like larger resources, higher education attainment, willingness to assume additional risks, and being white, strongly increase the probability of owning stocks. For

vehicle conditional on a choice in another is computed as equal to the unconditional (marginal) probability; ii) any joint probability of choices across different asset vehicles is computed as the product of the respective marginal probabilities.

²⁴ This probability is equal to the sum of the probabilities of all asset combinations in which at least one foreign asset is chosen, as shown in equation (15).

²⁵ We will discuss in detail the marginal effects from our multivariate model when separately examining investment in the three different foreign assets.

instance, having a college degree increases by 18 percentage points (pp) the probability of owning stocks directly, after controlling for resources and several indicators of financial attitudes and practices. Expectations about increases in future real income have a positive effect on direct stock holding, which is consistent with the predictions of intertemporal household portfolio models with background income risk and borrowing constraints (Cocco et al., 2005, Haliassos and Michaelides, 2003). More specifically, these models predict a positive investment in the risky asset for households that anticipate steeper future income profiles.²⁶ The existing empirical literature (see for example the contributions in Guiso et al., 2002) has attributed part of the estimated influence of education to this effect, since the more educated face upward-sloping income profiles; nevertheless, our results suggest that income and education have separate and significant effects. It is also worth mentioning that households that have members working in the financial sector now or in the past are also more likely to invest in stocks. This result is consistent with the view that directly held stocks represent a saving vehicle which is favored by investors familiar with the properties and the management of information-intensive investments. Using the Internet to collect financial information is also positively associated with investment in stocks, possibly because of the informational advantages and the lower monitoring costs that Internet use can bring about. All in all, results in the first stage indicate that directly held stocks are owned by a select group of investors characterized by large economic resources, low risk aversion and financial attitudes and practices that favor information-intensive investments.

When reporting the results from the second stage equation (Table 8, column 7), we show marginal effects on the probability of owning foreign stocks, *conditional* on owning any stocks at all. As already described, conditioning on the ownership of any stocks makes these marginal

²⁶ In those models, higher future income, although uncertain, implies a minimum guaranteed value of income at each future period that can serve as a surrogate riskless asset discounted by households, thus encouraging investment in stocks today.

effects reflect the influence of characteristics on foreign stock ownership that is over and above any influence such characteristics have on the overall participation decision. Therefore, these marginal effects should provide us with evidence for any participation hurdles that are particular to foreign stock ownership.

We find that, within the select group of stockowners, those with higher financial and real wealth, and with a sizeable inheritance received are significantly more likely to invest in foreign stocks. Furthermore, households willing to assume a higher than average financial risk have a higher probability of holding foreign stocks (4.1 pp) compared to their more risk-averse counterparts. Stockowners who extensively shop around for the very best terms before investing are more likely to own foreign stocks (2.7 pp) and the same holds for investors who have a long investment horizon (2.2 pp). We also estimate a positive effect for those who use Internet to get financial information (2.5 pp), a finding that could be due to the high informational requirements of foreign stocks, about which one can find considerable information on the Internet, typically in English as well. Notably, all these marginal effects are economically important, given that, as shown in Table 1, only about 10% of stock owners own foreign stocks.

On the other hand, variables denoting various expectations were not found significant. Expectations regarding the prospects of the US economy and/ or changes in interest rates, are likely to reflect anticipated benefits from international diversification. Yet, such anticipated benefits do not seem to induce ownership of foreign stocks. While race effects were positive and significant in the first stage, they are no longer significant and have the opposite sign in the second. This result suggests that, *ceteris paribus*, foreign stocks are equally popular among non-white stock owners.²⁷

²⁷ The SCF does not provide information on immigrant status but, to the extent that the immigrants are overrepresented in the group of non-whites, it may be the case that they opt for investments in foreign stocks of their

With reference to the variable that denotes obtaining financial information by asking other people, we estimate a negative association with foreign stockholding and an insignificant effect in the first stage. These findings appear, *prima facie*, to contradict those of Hong et al. (2004), who document a positive association between social interactions and stockholding (direct and through mutual funds). However, as they also point out this effect could work either way, because if the asset is widely held then prospective investors are likely to find in their social circle people who own it and can provide information about it (thus lowering participation costs). On the other hand, the likelihood of meeting someone who has invested in an asset that is only owned by few, like foreign stocks, is very small. In this case, as Hong et al. (2004) argue, social interaction effects are likely to amplify any given participation costs that foreign stocks entail, discouraging ownership of foreign securities.

Our results imply that some of the factors that could help households clear the unobserved threshold of participation in the stock market, and that appear significant in the first stage, have also an economically and statistically significant role in the decision to invest in foreign stocks. Given that these factors do not exhaust their influence in the first stage, they point to the existence of additional thresholds that stockholders have to overcome in order to invest in foreign stocks. Such thresholds may reflect information requirements about foreign accounting and tax practices, corporate relationships, rate of return calculations, and the legal system, as well as monetary costs of participation in foreign assets. In addition, there are non-tangible costs perceived by investors (e.g. time required to process information and trade assets in foreign markets), which are likely to be higher in foreign markets. Moreover, the lack of familiarity with companies that are headquartered outside the US is likely to amplify perceived participation

country of origin, given the lower information costs that this option would involve. More information on immigrant status is needed, however, in order to investigate this conjecture.

costs. Hence, it appears that households who own stocks directly do not view foreign stocks as a simple investment option that can increase their portfolio diversification and provide hedging against domestic market uncertainty. Rather, households perceive foreign stocks as a specialized investment that requires additional resources, good knowledge of foreign financial markets, and well-informed investment decision making. These requirements may be even stronger than what our estimates imply, given that we have to include in our investigation foreign stocks that are cross-listed in US stock exchanges, and thus should exhibit lower information and pecuniary costs than stocks that are not cross-listed.

Our findings shed also light on the profiles of investors who invest in assets such as foreign stocks. That is, investors with higher resources and certain investment attitudes, such as a higher willingness to assume financial risk, a longer investment horizon, and a greater propensity to shop around for investment alternatives, are more prone to investing in foreign stocks. In addition, we estimate a positive association with inheritance received and intentions to leave a sizeable bequest. We also find that poor health is likely to discourage investments in complicated and management-intensive assets, such as foreign stocks. These findings are consistent with the notable differences in the prevalence of various household characteristics (reported in Table 3 above) between owners of foreign stocks and the general population. In other words, the fact that foreign stock owners form a select group of investors is confirmed by our estimation results.

Marginal effects from the simple two-stage probit model for stocks are shown in columns 1-4 of Table 8. While the first stage effects differ very little from those of the multivariate model, those in the second stage, referring to the conditional probability of owning foreign stocks given ownership of any stocks, are very different. No variable exhibits any statistically significant effect in the simpler model. Consequently, one gets a very misleading picture of the effect of

household characteristics on foreign stockholding because these results imply that there are no additional obstacles for investors to overcome when considering this choice.

We also checked whether the effects of our main forcing variables of interest, i.e., those denoting participation costs and investment attitudes are time varying by interacting them with the survey year indicators. This set of variables consists of education, financial and real assets, labor income, risk preferences, investment horizon, Internet use, shopping around before investing, taking financial advice from friends and relatives, and working now or having worked in the past in the financial sector. We then performed a Wald test for the significance of these time-interacted terms in the foreign stock equation, as well as in the two other foreign assets, and in no case could we reject the null of no significance of the interaction terms. Therefore, it is quite unlikely that these variables have a time-varying effect on the propensity to hold foreign stocks, and the same is true for foreign bonds and liquid accounts.

4.3. Bonds and Foreign Bonds

Table 9 summarizes the results for bonds. To begin with, there are not any notable differences in the results from the multivariate and the two-stage probit. First stage results on bond ownership from the multivariate model (column 5) suggest that they are more likely to be held by the wealthier, the better educated, the whites, the married and those with long investment horizon. In contrast to stocks, indicators of financial attitudes and practices (extensively shop around for the best investment options and willingness to assume high risks) do not matter. Willingness to undertake risk is not significant either, which is expected given that bonds are generally considered safer than stocks. However, bond ownership is encouraged by social interactions. An expected decrease in real income augments the probability to own bonds, possibly because they reduce overall portfolio risk in unfavourable circumstances.

On the other hand, the effects on the conditional probability of foreign bond ownership are small and insignificant (except for time effects), suggesting that once the threshold of any bond ownership is overcome, there are small or no additional costs of investment in foreign bonds.²⁸

4.4. Liquid Accounts and Accounts in Foreign Currency

Turning to the liquid accounts (Table 10), we observe that the multivariate probit and the simpler two-stage probit produce similar results for the first stage, but less so for the second one. Results from the first stage suggest that households with low resources, as well as those with non-white, low educated, retired and unemployed heads are less likely to own a liquid account. This same is true for single males, those in poor health as well as households with problems in obtaining credit. These findings are consistent with empirical studies that investigate the characteristics of households who do not have any liquid accounts (see for instance Rhine et al., 2001). Some of the factors that have been suggested as explanations for no ownership of bank accounts include households' lack of resources, inability to manage an account, preference not to deal with banks and to maintain privacy in financial matters, poor credit histories as well as the existence of monetary costs and fees, mainly minimum balance requirements and service charges (see Aizcorbe et al., 2003, and Hogarth et al., 2004).

We also find that investors who save for precautionary reasons are more likely to have a liquid account. The same holds for those who use the Internet to obtain financial information, possibly because this way they can monitor and manage their savings more easily. Those who expect the US economy to do worse are less likely to have a bank account (possibly because they fear the repercussions of a downturn on the financial system), while those who expect a lower

²⁸ We cannot estimate the effect of bad health on foreign bonds because bad health perfectly predicts no foreign bond ownership.

real income in the future are more likely to have a bank account, maybe as part of a defensive investment strategy. On the other hand, the effects of financial practices, like systematic shopping for the best investment options and long investment horizon, are small in magnitude or insignificant.

Marginal effects on the probability of owning accounts in foreign currency conditional on ownership of any liquid account are displayed in column 7 of Table 10. We notice that, and in contrast to foreign stocks, almost none of the factors that might help overcome informational or pecuniary costs (i.e., length of investment horizon, using the Internet, shopping around for the best terms before investing, discussing financial choices with others, non-investment income) matter for having a foreign account, the only exception being working now or in the past in the financial sector (0.3 pp). In addition, the effect of the willingness to assume higher risk is significant in the second stage (0.5 pp), possibly reflecting the exchange rate risk that account holders need to assume in order to invest in foreign currency. This effect is, however, quantitatively much smaller than the corresponding one derived for foreign stocks, which involve additional uncertainties related to the performance of the stock market. Finally, those who expect an increase in domestic interest rates are less likely to invest money into foreign accounts (-0.2 pp, significant at 10%), which makes economic sense given that higher domestic interest rates make liquid accounts in the US relatively more attractive. Given that, as shown in Table 1, only about 2.5% of those with liquid accounts in any form have any of them denominated in a foreign currency, the aforementioned statistically significant marginal effects are economically significant as well.

5. Conclusions

The limited investment in foreign assets by US households is notable because it can imply large foregone gains from international diversification. We study this phenomenon in a way that distinguishes between investments in general and those in foreign assets in particular, and we apply this approach to stocks, bonds, and liquid accounts held directly. To that effect, we construct a flexible multivariate probit model that allows households to clear different participation hurdles in order to invest domestically and abroad, while taking into account the fact that those who have invested in the asset in the first place possess a different configuration of characteristics from the general population, i.e., they form a selected sample. In addition, we allow for the interdependence of all decisions through the correlations of their unobservables, and show how one can calculate economically meaningful magnitudes (probabilities and marginal effects) out of this multi-equation discrete choice model while taking into account the full spectrum of the correlations between unobservables.

A novel result of our analysis is that households face obstacles in investing in foreign stocks directly that are separate from those affecting investment in domestic stocks and require economic resources and financial sophistication to be overcome. This finding suggests that even small entry costs associated with investments abroad can generate specialization in domestic securities, just as participation costs in domestic markets can lead to lack of investment in stocks in lifecycle models with liquidity constraints and background income risk. We find no such evidence for foreign bonds while for liquid accounts there is some evidence for the presence of participation thresholds, which are, however, much weaker than those for foreign stocks.

Furthermore, our results point to the existence of a negative association between asking relatives, friends and work contacts for financial advice and the likelihood to invest in foreign stocks. This result corroborates the conjecture by Hong et al. (2004) that social interactions are

likely to discourage investment in foreign stocks, given their limited popularity. We also show that accounting for interrelationships among different investment decisions through our multivariate probit model that corrects for selectivity is important because: i) foreign stock owners form a selected sample and thus are not representative of the general population; ii) ignoring correlations of unobservables across the three saving vehicles leads to very misleading results for the effects of characteristics on foreign stock ownership and often to inferior predictions of population asset choices, and is also strongly rejected statistically.

Finally, our results point to the importance of household financial literacy (Lusardi and Mitchell, 2007, Van Rooij et al., 2011), because they imply that there is a need for a better grasp of financial issues even among households that have already invested in stocks directly. Even though such households are typically wealthier, better educated, and more financially sophisticated than average, only a small minority among them seems to perceive the benefits of international diversification and thus invests in foreign stocks. Awareness of such benefits can increase the portfolio performance for households that already participate in the stock market, as well as make stockholding more appealing for households that do not own any stocks.

Table 1. Prevalence of Asset Ownership

Year	Directly held stocks	Foreign stocks (among stock owners)	Directly held bonds	Foreign bonds (among bond owners)	Liquid accounts	Foreign liquid accounts (among liquid account owners)
1995	15.3	1.2 (8.0)	24.7	0.2 (0.8)	87.4	1.5 (1.7)
1998	19.2	2.1 (10.9)	21.5	0.1 (0.4)	90.6	1.8 (2.0)
2001	21.3	2.1 (9.7)	18.8	0.2 (0.9)	91.4	3.1 (3.4)
2004	20.7	2.4 (11.5)	18.8	0.1 (0.4)	91.3	2.7 (2.9)

Notes: SCF 1995, 1998, 2001, 2004, weighted data. The reported statistics are corrected for multiple imputation. Liquid Accounts include all types of transaction accounts (checking, savings, money market and call) comprising even the few of those with zero reported balances. Stocks refer to directly held stocks which are publicly traded. Bonds include US government savings bonds and other types of bonds (tax-exempt, mortgage-backed, US government/agency and other).

Table 2. Combinations of Foreign Asset Investment among Foreign Asset Owners

Foreign stocks	Foreign bonds	Foreign liquid accounts	Percentage owning the combination
Yes	No	No	42.8
No	Yes	No	2.3
No	No	Yes	51.0
Yes	Yes	No	0.5
No	Yes	Yes	0.4
Yes	No	Yes	2.9
Yes	Yes	Yes	0.0

Notes: See Table 1.

Table 3. Distribution of Household Characteristics

Variable	Whole sample	Owns only foreign stocks	Has only foreign liquid accounts
Age (mean)	48.9	53.6	48.9
High school graduate	0.509	0.297	0.481
College degree or more	0.337	0.683	0.430
Married	0.588	0.676	0.629
Single male	0.140	0.176	0.148
Has children	0.435	0.378	0.394
White	0.762	0.898	0.795
Poor health	0.061	0.019	0.033
Uses Internet to obtain financial information	0.111	0.260	0.147
Asks Friends/Relatives/Work contacts for financial information	0.360	0.331	0.358
Extensively "shops around"	0.157	0.239	0.156
Expects US economy to do better	0.312	0.335	0.339
Expects US economy to do worse	0.251	0.224	0.229
Expects US interest rates to go higher	0.683	0.680	0.614
Expects US interest rates to go lower	0.063	0.064	0.079
Expects future income to rise faster than prices	0.220	0.277	0.237
Expects future income to rise lower than prices	0.305	0.280	0.299
Investment horizon > 10 yrs	0.143	0.236	0.125
Willingness to take above average financial risk	0.205	0.447	0.298
Intention to leave a bequest	0.293	0.542	0.301
Has received inheritance	0.199	0.459	0.196
Credit constrained	0.224	0.076	0.189
Last year's income unexpectedly low	0.171	0.162	0.156
Works/ed in the Financial Sector	0.204	0.259	0.253
Saves for "rainy days"	0.300	0.297	0.324
Self-employed	0.113	0.209	0.138
Retired	0.240	0.233	0.213
Unemployed/Inactive	0.051	0.025	0.047
Non-investment income (median)	37,788	69,076	44,153
Net real wealth (median)	57,968	219,359	68,783
Net financial wealth (median)	9,943	384,092	27,920

Notes: SCF 1995, 1998, 2001, 2004, weighted data. The reported statistics are corrected for multiple imputation. Numbers denote prevalence, except for age (mean), non-investment income, net real wealth, net financial wealth (medians in 2004 prices).

Table 4. Model Specification

Eqn.	Outcome	Latent propensities	Observed binary outcomes
For each respondent $i = 1, \dots, N$:			
(1)	Owens any Stocks	$S_i^* = C_i' \alpha + v_i$	$S_i = I(S_i^* > 0)$
(2)	Owens Foreign Stocks	$FS_i^* = D_i' \beta + u_i$	$FS_i = I(FS_i^* > 0)$ if $S_i=1$, else unobserved
(3)	Owens any Bonds	$B_i^* = G_i' \gamma + v_i$	$B_i = I(B_i^* > 0)$
(4)	Owens Foreign Bonds	$FB_i^* = H_i' \delta + n_i$	$FB_i = I(FB_i^* > 0)$ if $B_i=1$, else unobserved
(5)	Has any Liquid Accounts	$A_i^* = X_i' \zeta + \varepsilon_i$	$A_i = I(A_i^* > 0)$
(6)	Has Foreign Liquid Accounts	$FA_i^* = Y_i' \theta + e_i$	$FA_i = I(FA_i^* > 0)$ if $A_i=1$, else unobserved
(7)	Error terms $(v_i, u_i, v_i, n_i, \varepsilon_i, e_i) \sim N(0, \Omega)$, where Ω is a symmetric matrix with typical element $\rho_{ij} = \rho_{ji}$ for $i, j \in \{v, u, v, n, \varepsilon, e\}$ and $i \neq j$, and $\rho_{jj} = 1$, for all j , and N_6 denotes a 6-variate normal distribution. The errors in each equation are assumed to be orthogonal to the predictors		

Notes: $I(\cdot)$ is the indicator function equal to one if its argument is true, and zero if false.

Table 5. Multivariate Probit with Selection: Estimates of Cross-Equation Correlations

Figure 1. Graphical Representation of the Model

Appendix

A.1. Likelihood Function

As in Jenkins *et al.* (2006) we use the indices $k_T=2T-1$ for $T \in \{S, FS, B, FB, A, FA\}$, and represent the q -variate normal distribution by $N_q(\cdot)$. As an example, if the household holds directly any stocks then $k_S=1$, while if the household has (not) any foreign stocks $k_{FS}=1$ (-1). On the other hand, if the household does not own any stocks directly then $k_S=-1$ and the equation for foreign stocks (equation (2)) does not appear in the likelihood term of that particular household. The equations for bonds and liquid accounts and their foreign counterparts appear in the likelihood in an analogous fashion. As a result, the likelihood terms corresponding to the eight possible cases of first-stage asset holdings can be written as follows (dropping for simplicity the subscript i denoting households):

- 1) The household holds directly neither stocks, nor bonds nor liquid accounts:

$$L_1 = N_3(k_S C' \alpha, k_B G' \gamma, k_A X' \zeta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}) \quad (\text{A.1})$$

with $k_S = k_B = k_A = -1$

- 2) The household invests directly in stocks but does not hold directly any bonds and does not have liquid accounts:

$$L_2 = N_4(k_S C' \alpha, k_{FS} D' \beta, k_B G' \gamma, k_A X' \zeta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FS} \rho_{ue}, k_{FS} k_B \rho_{uv}, k_{FS} k_A \rho_{ue}) \quad (\text{A.2})$$

with $k_S = 1, k_B = k_A = -1, k_{FS} = \pm 1$

- 3) The household invests directly in bonds but does not hold directly any stocks and does not have liquid accounts:

$$L_3 = N_4(k_S C' \alpha, k_B G' \gamma, k_{FB} H' \delta, k_A X' \zeta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FB} \rho_{vn}, k_B k_{FB} \rho_{vn}, k_{FB} k_A \rho_{ne}) \quad (\text{A.3})$$

with $k_B = 1, k_S = k_A = -1, k_{FB} = \pm 1$

- 4) The household has liquid accounts but holds directly neither stocks nor bonds:

$$L_4 = N_4(k_S C' \alpha, k_B G' \gamma, k_A X' \zeta, k_{FA} Y' \theta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FA} \rho_{ue}, k_B k_{FA} \rho_{ve}, k_A k_{FA} \rho_{ee}) \quad (\text{A.4})$$

with $k_A = 1, k_S = k_B = -1, k_{FA} = \pm 1$

- 5) The household holds directly both stocks and bonds but has no liquid accounts:

$$L_5 = N_5(k_S C' \alpha, k_{FS} D' \beta, k_B G' \gamma, k_{FB} H' \delta, k_A X' \zeta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FS} \rho_{ui}, k_{FS} k_B \rho_{uv}, k_{FS} k_A \rho_{ue}, k_S k_{FB} \rho_{ui}, k_B k_{FB} \rho_{vi}, k_{FB} k_A \rho_{ne}, k_{FS} k_{FB} \rho_{ui}) \quad (\text{A.5})$$

with $k_A = -1, k_S = k_B = 1, k_{FS} = \pm 1, k_{FB} = \pm 1$

- 6) The household holds directly bonds, has liquid accounts but has no direct stock holdings:

$$L_6 = N_5(k_S C' \alpha, k_B G' \gamma, k_{FB} H' \delta, k_A X' \zeta, k_{FA} Y' \theta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FB} \rho_{ui}, k_B k_{FB} \rho_{vi}, k_{FB} k_A \rho_{ne}, k_S k_{FA} \rho_{ue}, k_B k_{FA} \rho_{ve}, k_A k_{FA} \rho_{ee}, k_{FB} k_{FA} \rho_{ne}) \quad (\text{A.6})$$

with $k_S = -1, k_B = k_A = 1, k_{FB} = \pm 1, k_{FA} = \pm 1$

- 7) The household holds directly stocks and has liquid accounts but has no direct bond holdings:

$$L_7 = N_5(k_S C' \alpha, k_{FS} D' \beta, k_B G' \gamma, k_A X' \zeta, k_{FA} Y' \theta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FS} \rho_{ui}, k_{FS} k_B \rho_{uv}, k_{FS} k_A \rho_{ue}, k_S k_{FA} \rho_{ue}, k_B k_{FA} \rho_{ve}, k_A k_{FA} \rho_{ee}, k_{FS} k_{FA} \rho_{ue}) \quad (\text{A.7})$$

with $k_B = -1, k_S = k_A = 1, k_{FS} = \pm 1, k_{FA} = \pm 1$

- 8) The household holds directly stocks and bonds and has liquid accounts:

$$L_8 = N_6(k_S C' \alpha, k_{FS} D' \beta, k_B G' \gamma, k_{FB} H' \delta, k_A X' \zeta, k_{FA} Y' \theta; k_S k_B \rho_{uv}, k_S k_A \rho_{ue}, k_B k_A \rho_{ve}, k_S k_{FS} \rho_{ui}, k_{FS} k_B \rho_{uv}, k_{FS} k_A \rho_{ue}, k_S k_{FB} \rho_{ui}, k_B k_{FB} \rho_{vi}, k_{FB} k_A \rho_{ne}, k_S k_{FA} \rho_{ue}, k_B k_{FA} \rho_{ve}, k_A k_{FA} \rho_{ee}, k_{FS} k_{FB} \rho_{ui}, k_{FB} k_{FA} \rho_{ne}, k_{FS} k_{FA} \rho_{ue}) \quad (\text{A.8})$$

with $k_S = k_B = k_A = 1, k_{FA} = \pm 1, k_{FB} = \pm 1, k_{FA} = \pm 1$

Thus the overall contribution to the log likelihood by a given household is equal to

$$\begin{aligned}
\log L = & (1-S)(1-B)(1-A) \log L_1 + S(1-B)(1-A) \log L_2 + \\
& (1-S)B(1-A) \log L_3 + (1-S)(1-B)A \log L_4 + SB(1-A) \log L_5 + \\
& (1-S)BA \log L_6 + S(1-B)A \log L_7 + SBA \log L_8
\end{aligned} \tag{A.9}$$

A.2. Estimates and Standard Errors of Probabilities and Marginal Effects

Since probabilities, marginal effects and semi-elasticities are nonlinear functions $g(\hat{\psi})$ of the estimated parameters $\hat{\psi} = (\hat{\alpha}, \hat{\beta}, \hat{\gamma}, \hat{\delta}, \hat{\zeta}, \hat{\theta}, \hat{\rho})$, we compute their point estimates (expected values) and standard errors using Monte Carlo simulation (Train, 2003), that is

$$E(g(\psi)) = \int g(\psi) f(\psi) d\psi \tag{B.1}$$

where $f(\psi)$ denotes the joint distribution of all the elements in ψ . We implement this simulation estimator by drawing from the distribution of the parameters $\hat{\psi}$ under the assumption that they are distributed asymptotically normally with means and variance-covariance matrix equal to the maximum likelihood estimates. At each parameter draw we generate for all households probabilities and marginal effects and then calculate $g(\hat{\psi})$ as their weighted average (median) across households.²⁹ We then estimate $E(g(\psi))$ as the average of $g(\hat{\psi})$ across draws, and the standard error of $g(\psi)$ as the standard deviation of the distribution of $g(\hat{\psi})$ across draws.

A.3. Calculation of predicted asset choices

The predicted population proportions are obtained as follows:

²⁹ We avoid evaluating probabilities or marginal effects at sample means/medians since this practice can lead to severely biased results (see Train, 2003, pp. 33-34).

- 1) Using the Monte Carlo draws of the estimated coefficients, as discussed in Appendix A.2 above, we compute the probability of a given asset choice for every household at a given coefficient draw.
- 2) For each household, we randomly draw a number from a (0,1) uniform distribution, and if it is smaller than the predicted probability we predict that the household makes the asset choice, while the opposite happens if the random number is greater than the predicted probability. Repeating this procedure for all households allows us to compute the predicted proportion of households that make the asset choice, for a given draw of the coefficients.

We repeat 1) and 2) for every coefficient draw and obtain point estimates and standard errors of predicted proportions by simulation as described in Appendix A.2.
